I. Development

Recap on “Part E. MDP with model”

- Following is the list of sections of the lecture notes in Part E.

- Lecture note E1

1. Introduction and Preview
2. Setting
3. Policy Evaluation 1
4. Policy Evaluation 2

- Lecture note E2

1. Recap
2. Policy improvement ✓
3. Policy iteration ✓

- Lecture note E3

1. Value improvement
2. Value iteration

- In the previous lecture F1, we discussed two policy evaluation method without the knowledge of the model. Namely, MC policy evaluation and TD policy evaluation.
- Thus, today's lecture must be on how to improve an policy without knowledge of the model, using the policy evaluation in the previous lecture F1.

(mc, TD)

Recap on policy improvement with knowledge of model

- In **F1**, we successfully evaluated $V^{\pi^{speed}}$ and $V^{\pi^{50}}$
- Let's first review our approach at E2. Sec 2. Policy improvement.
- In E2, p8 we criticized π^{speed} as follows.

*From the state '60', current policy gives the estimate for the state-value function of -1.67. (However), we know that switching to *normal mode* at state '60' is better alternative than current action of *speed mode*. Because it guarantess the arrival to the state '70' with additional energy spending of 1.0.*

$$g^{\pi}(s, a)$$

- In other words, from state '60',
 - Choosing normal mode gives

$$R + \gamma PV = -1.0 + 1.0 \cdot 0 = -1.0$$
 - Choosing speed mode gives

$$R + \gamma PV = -1.5 + (0.9 \cdot 0 + 0.1 \cdot -1.74) = -1.674$$
- Is this applicable to our current situation?

$$g^{\pi}(s, a = \text{normal})$$

vs

$$g^{\pi}(s, a = \text{speed})$$

Issue 1 - can't evaluate $R + \gamma \mathbf{P} \underline{V}$

- **Issue 1:** Even after evaluating V , unattainable is $\underline{R + \gamma \mathbf{P} V}$ because we lack the knowledge of R and $\underline{\mathbf{P}}$.
- To find an alternative, let's again review the policy improvement with knowledge of the model.
- In E2, p20, it states,

Policy improvement occurs by

$$\pi^{new}(s) \leftarrow \operatorname{argmax}_{a \in \mathcal{A}} \boxed{q^{\pi^{old}}(s, a)}$$

, or, equivalently,

$$\pi^{new}(s) \leftarrow \operatorname{argmax}_{a \in \mathcal{A}} \left[R(s, a) + \gamma \sum_{\forall s'} \overset{\uparrow}{P_{ss'}^a} V^{\pi^{old}}(s') \right], \text{ for all } s$$

$$q(s, a) = R(s, a) + \gamma \mathbf{P} V^{\pi}(s)$$

Handwritten notes: The equation $q(s, a) = R(s, a) + \gamma \mathbf{P} V^{\pi}(s)$ is written in red. The term $q(s, a)$ is circled in blue. The term $R(s, a)$ has a red arrow pointing up to it. The term $\gamma \mathbf{P} V^{\pi}(s)$ has a red arrow pointing up to it. Below the equation, there is a sequence of boxes containing the letters s, a, s, a, s, a with arrows pointing between them, and a sequence of numbers $-1, 1, 0, n, -1, \dots$ with arrows pointing between them.

- **Resolution to the Issue 1:** Use the first way of involving q -function, not the second way of involving value function. Let's go back to policy evaluation and evaluate $q^{\pi}(s, a)$, instead of $V^{\pi}(s)$.

Issue 2 - may not collect all combination of (s, a) for $q^\pi(s, a)$.

- Going back to π^{speed} , the agent always chooses speed mode at the state 60. So there is no way we may collect sample of $q^{\pi^{speed}}(60, \text{"normal"})$ no matter how many episode we generates.
- In other words, from a deterministic policy π , we can't find an improvement toward the action that current π does not ever take.
- Choosing a random policy π^{50} could be an alternative? We can do one-step improvement from π^{50} , but it will become a deterministic policy again. Then, we are stuck again.
- Policy improvement without model ~~knowledge~~, thus cannot be done with "greedy way". It must allow some relaxation of **not choosing the best out of experienced history**. We call this as **exploration**.
- In other words, the improved policy must be a **random policy**. The improved policy needs to take every action a with some positive probability. By doing so, the improved policy will explore actions even if the action is sub-optimal to the current policy evaluation.

- Then, how to improve policy to a random policy?
- We introduce a ϵ -greedy ^{Policy} action, which is
 1. (exploitation) to choose the best action under the policy evaluation with probability $1 - \epsilon$
 2. (exploration) or, to choose uniformly random action among all available actions with probability ϵ .
- In other words, ϵ -greedy ^{Policy} action is
 - to exploit with probability $1 - \epsilon$
 - and to explore with probability ϵ .
- There exists exploit-explore dilemma, which is an important concept in reinforcement learning.
- Does ϵ -greedy always improve?
 - Remind that greedy action ^{Policy} in Part E, finds an action according to the current value estimate and then follow a policy π afterwards. It was an improvement over π .
 - Likewise, ϵ -greedy action ^{Policy} finds an action according to the current value estimate with probability $1 - \epsilon$ and then follow a policy π afterwards. It is an improvement over π .

- We are to iterative policy, where each iteration involves an policy evaluation and policy improvement.
- Then, how should you choose the value of ϵ to reach the optimal policy?
 - ✓ 1. We need ϵ to be large enough so that proper exploration take places among all possible actions.
 2. On the other hand, remind that the optimal policy is guaranteed to be deterministic policy. We do not want produce the ultimate outcome that is randomizing action sets. $\epsilon \rightarrow 0$
- Desired properties of ϵ is stated as below. In other words, π must be iteratively improved in a GLIE way.

Definition 1 (GLIE)

A policy π is called Greedy in the Limit of Infinite Exploration (GLIE) if

- (Exploration) All state-action pairs are visited an **infinite** number of times.
- (Exploitation) The policy must be **converged** to the policy that is greedy with respect to the learned Q-function.

Remark 1

An ϵ -greedy policy where $\epsilon = \frac{1}{i}$ (i is the episode number) is **GLIE**. This is because

- $\sum_{i=1}^{\infty} \frac{1}{i} = \infty$ (exploration)
- $\frac{1}{i} \rightarrow 0$, as $i \rightarrow \infty$ (exploitation)

Handwritten notes:

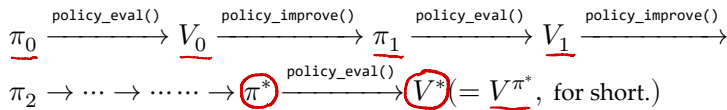

$$\sum_{i=1}^{\infty} \frac{1}{i} = \infty \quad \checkmark$$

$$\lim_{i \rightarrow \infty} \frac{1}{i} = 0 \quad \checkmark$$

II. Strategy

Policy iteration process

- Policy iteration process was described as follows (E2, p15)

- When model was known to the agent, policy evaluation was conducted until very accurate evaluation is done. This is because the process used fixed point theorem that is relatively fast.
- However, when model is not known, policy evaluation using many sample paths take long time, because the sample paths need be generated prior to evaluation. Thus, general approach is to use only small number of sample path (often, only one sample path) to do policy evaluation and then proceed to policy improvement.

- This makes the general process of policy iteration to contain higher number of iterations of policy evaluation and policy improvement.
- The MC policy iteration process is summarized as follows: (MC control)
 0. Initialize $q(s, a)$
 1. Begin with a policy π
 2. Generate a sample path using the current π (`simul_path()`)
 3. Evaluate the current policy π and update $q(s, a)$ (`pol_eval_MC()`)
 4. Improve the policy into a ϵ -greedy policy using $q(s, a)$ (`pol_imp()`)
 5. Repeat 2-4 many times (*why not until policy converges?*)
- The TD policy iteration process is summarized as follows: (TD control).
 0. Initialize $q(s, a)$
 1. Begin with a policy π
 2. Begin a new sample path from the state s
 3. Proceed a time step to generate subsequent a, r, s', a' (`simul_step()`)
 4. Evaluate the current policy π and update $q(s, a)$ (`pol_eval_TD()`)
 5. Improve the policy into a ϵ -greedy policy using $q(s, a)$ (`pol_imp()`)
 6. Repeat 3-5 until the episode ends.
 7. Repeat 2-6 many times (*why not until policy converges?*)
- Rest of this note will create the source code `skier.R` that contains the functions above.
